WEEK 7 MODULE

File Handling in PHP

INTRODUCTION

File handling is a crucial aspect of programming that involves creating, reading, writing, and deleting files. In PHP, file handling plays a vital role in web development, especially when dealing with tasks such as data storage, retrieval, and manipulation. Understanding file handling in PHP requires knowledge of the functions and techniques available to effectively perform these tasks.

PHP provides a rich set of built-in functions for file handling, which can be used to perform a variety of operations on files, including opening, reading, writing, and closing files. With a good understanding of file handling in PHP, developers can create powerful web applications that can handle various file-related tasks efficiently.

PHP provides several built-in functions like open (), fwrite(), fread(), fclose(), and others to manipulate files in different modes like read, write, append, binary, etc. PHP also provides functions to manage directories, such as opendir() to open a directory, readdir() to read the contents of a directory and closedir() to close a directory. These functions enable developers to create, move, rename, delete, and manage files and directories.

PHP fopen() Function

The fopen() function in PHP is used to open a file or URL and returns a file pointer resource that can be used to read, write, or manipulate the file.

The syntax of fopen() is as follows:

```
resource fopen ( string $filename , string $mode [, bool $use_include_path = false [, resource $context ]] )
```

In this syntax:

- $filename is the name of the file or URL to open
- $mode is the mode in which to open the file. This can be one of the following:
- 'r': read-only
- 'w': write only (truncates the file to zero length or creates a new file)
- 'a': append-only (opens the file for writing at the end of the file)

- 'x': exclusive write (creates a new file and opens it for writing only if it doesn't already exist)
- 'b': binary mode (used in conjunction with the above modes to indicate that the file should be opened in binary mode)
- 't': text mode (used in conjunction with the above modes to indicate that the file should be opened in text mode)
- $use_include_path is a boolean parameter that indicates whether to search for the file in the include path (if set)
- $context is an optional parameter that allows you to specify a context for the file stream (e.g. HTTP headers, SSL settings, etc.)

Here's an example that demonstrates how to use fopen() to open a file in read-only mode, read its contents line by line, and then close the file:

```php
$file = fopen('example.txt', 'r');

if ($file) {
    while (($line = fgets($file)) !== false) {
        echo $line;
    }
    fclose($file);
}
```

Explanation

In this example, the file example.txt is opened in read-only mode using fopen(). The while loop reads the file line by line using the fgets() function, and the contents of each line are echoed to the screen. Finally, the fclose() function is called to close the file.

PHP fclose() Function

The PHP fclose() function is used to close an open file pointer or handle in PHP. It is typically used after a file has been opened using fopen() or a related function.

Here is the syntax for the fclose() function:

```php
bool fclose ( resource $handle )
```

The function takes a single parameter, which is the file pointer or handles to be closed. The function returns a boolean value indicating whether the file was successfully closed or not.

Here's an example that demonstrates how to use fclose() in PHP:

```
// Open a file for writing
$file = fopen("example.txt", "w");

// Write some data to the file
fwrite($file, "Hello, world!");

// Close the file
fclose($file);
?>
```

PHP fread() Function

The PHP fread() function is used to read a specified number of bytes from a file. It is a file-handling function in PHP that allows you to read data from a file. Syntax:

```
fread($file_handle, $length)
```

Parameters:

$file_handle: Required. Specifies the file pointer or file handle to read from. $length: Required. Specifies the number of bytes to read from the file.

Return Value: Returns the read data as a string.

Example:

Suppose we have a file example.txt with the following content:

```
Hello, World! This is an example file.
```

And we want to read the first 10 bytes of this file using the fread() function. Here's how we can do that:

```php
<?php

$file_handle = fopen("example.txt", "r"); // opening the file in read mode

$length = 10; // specifying the number of bytes to read

$data = fread($file_handle, $length); // reading the first 10 bytes from the file

fclose($file_handle); // closing the file

echo $data; // output: Hello, Wor
?>
```

PHP fwrite() Function

The PHP fwrite() function is used to write data to a file. It takes three parameters: a file pointer, a string to be written, and an optional parameter that specifies the maximum number of bytes to write.

Here's the syntax of the fwrite() function:

```php
fwrite ( resource $handle , string $string [, int $length ] ) : int|false
```

- resource $handle: A file pointer, which is a reference to the opened file. It can be obtained using functions such as fopen(), fsockopen(), and tmpfile().
- string $string: The string to be written to the file.
- int $length: An optional parameter that specifies the maximum number of bytes to be written. If this parameter is not specified, all the data in the string will be written to the file.

The fwrite() function returns the number of bytes written to the file, or false on error.

Here's an example of how to use the fwrite() function to write data to a file:

```php
$file = fopen("data.txt", "w");

if ($file) {
    $data = "Hello, World!\n";
    fwrite($file, $data);
    fclose($file);
    echo "Data written to the file.";
} else {
    echo "Error opening file.";
}
```

Explanation

In this example, we first open a file named "data.txt" in write mode using the fopen() function. We then check if the file was successfully opened, and if it was, we write the string "Hello, World!\n" to the file using the fwrite() function.

PHP Delete File - unlink()

In PHP, the unlink() function is used to delete a file from the file system. It accepts a single argument, which is the path to the file that needs to be deleted.

Here is the syntax of the unlink() function:

```
bool unlink ( string $filename [, resource $context ] )
```

Here is an example of using the unlink() function to delete a file:

```php
<?php
$file_path = '/path/to/file.txt';

if (file_exists($file_path)) {
    if (unlink($file_path)) {
        echo "File deleted successfully.";
    } else {
        echo "Unable to delete the file.";
    }
} else {
    echo "File does not exist.";
}
?>
```

Explanation

In this example, we first check if the file exists using the file_exists() function. If the file exists, we attempt to delete it using the unlink() function. If the unlink() function returns true, we display a success message. If it returns false, we display an error message.

It is important to note that the unlink() function permanently deletes the file, so be careful when using it. Once a file is deleted using unlink(), it cannot be recovered.

Conclusion

- File handling in PHP involves opening, reading, writing, and manipulating files stored on a file system.

- The fopen() function is used to open a file for reading, writing, or appending.
- The fwrite() function is used to write to a file, while the fread() function is used to read from a file.
- The fgets() function can be used to read a single line from a file.
- The fclose() function should be used to close a file after reading or writing to it.

UPLOADING AND MANIPULATING FILES

Uploading and manipulating files in PHP is a common task when building web applications. You can use PHP to handle file uploads from HTML forms, store them on the server, and perform various operations like renaming, resizing, or moving files. Here's a step-by-step guide on how to accomplish this:

Create an HTML Form:

First, create an HTML form that allows users to upload files. Use the <form> element with the enctype attribute set to "multipart/form-data" to enable file uploads. Include an <input type="file"> field for file selection.

```html
<html>
<head></head>
<body>
    <h1>File Upload</h1>
    <form action="upload.php" method="POST" enctype="multipart/form-data">
        <input type="file" name="fileToUpload" id="fileToUpload">
        <input type="submit" value="Upload File" name="submit">
    </form>
</body>
</html>
```

Create a PHP Upload Script:

Create a PHP script (upload.php in this example) to handle the file upload process. Here's a basic script that demonstrates file upload:

```php
<?php
if (isset($_POST["submit"])) {
    $targetDirectory = "uploads/"; // Specify the directory where you want to save uploaded files
    $targetFile = $targetDirectory . basename($_FILES["fileToUpload"]["name"]);
    $uploadOk = true;

    // Check if the file already exists.
    if (file_exists($targetFile)) {
        echo "File already exists.";
        $uploadOk = false;
    }

    // Check file size (you can set a maximum size if needed).
    if ($_FILES["fileToUpload"]["size"] > 5000000) { // 5MB limit
        echo "File is too large.";
        $uploadOk = false;
    }

    // Allow only specific file types (e.g., image files).
    $allowedExtensions = array("jpg", "jpeg", "png", "gif");
    $fileExtension = strtolower(pathinfo($targetFile, PATHINFO_EXTENSION));

    if (!in_array($fileExtension, $allowedExtensions)) {
        echo "Only JPG, JPEG, PNG, and GIF files are allowed.";
        $uploadOk = false;
    }

    // Check if $uploadOk is set to false by any of the checks above.
    if (!$uploadOk) {
        echo "File was not uploaded.";
    } else {
        // Move the uploaded file to the specified directory.
        if (move_uploaded_file($_FILES["fileToUpload"]["tmp_name"], $targetFile)) {
            echo "The file " . basename($_FILES["fileToUpload"]["name"]) . " has been uploaded.";
        } else {
            echo "Error uploading the file.";
        }
```

This PHP script does the following:

- Checks if a file with the same name already exists in the target directory.
- Checks the file size to ensure it's within acceptable limits.
- Restricts file types to a predefined set (you can customize this).
- Moves the uploaded file to the specified directory if all checks pass.

File Manipulation:

After uploading the file, you can perform various manipulations, such as resizing images, processing text files, or renaming files. Here are some examples:

Image Resizing (if the uploaded file is an image): To resize images, you can use a library like GD or ImageMagick. Here's an example using GD:

```php
<?php
// Check if it's an image (you may need to adjust the allowed extensions).
if (in_array($fileExtension, array("jpg", "jpeg", "png", "gif"))) {
    // Load the image.
    $image = imagecreatefromjpeg($targetFile); // Change function based on file type.

    // Resize the image to a new width and height.
    $newWidth = 300;
    $newHeight = 200;
    $resizedImage = imagecreatetruecolor($newWidth, $newHeight);
    imagecopyresampled($resizedImage, $image, 0, 0, 0, 0, $newWidth, $newHeight, imagesx($image), imagesy($image));

    // Save the resized image.
    imagejpeg($resizedImage, "uploads/resized_" . basename($_FILES["fileToUpload"]["name"]));

    // Clean up resources.
    imagedestroy($image);
    imagedestroy($resizedImage);
}

?>
```

Renaming Files: You can rename the uploaded file using the rename() function.

```php
<?php

$newFileName = "new_file_name." . $fileExtension;
rename($targetFile, $targetDirectory . $newFileName);

?>
```

Remember to create the uploads directory in your project to store the uploaded files, and ensure it has the necessary permissions for file uploads to work. Also, be cautious when handling user-uploaded files to prevent security vulnerabilities, such as file inclusion attacks or malicious file uploads. Implement further validation and security measures as needed for your specific application.

MANAGING FILE DIRECTORIES AND PERMISSIONS IN PHP

Managing file directories and permissions in PHP involves working with the filesystem functions provided by PHP and ensuring that the web server has the necessary permissions to perform these operations. Here are some common tasks related to managing file directories and permissions in PHP:

1. **Creating a Directory:**

To create a new directory in PHP, you can use the mkdir function:

```
$directoryPath = 'path/to/new_directory';
mkdir($directoryPath);
```

Make sure that the directory path is writable by the web server user.

2. **Checking if a Directory Exists:**

You can check if a directory exists using the is_dir function:

```
$directoryPath = 'path/to/check';
if (is_dir($directoryPath)) {
    echo 'Directory exists';
} else {
    echo 'Directory does not exist';
}
```

3. **Listing Directory Contents:**

To list the files and subdirectories within a directory, you can use the *scandir* function:

```
$directoryPath = 'path/to/list';
$contents = scandir($directoryPath);
foreach ($contents as $item) {
    echo $item . "<br>";
}
```

4. **Deleting a Directory**:

To delete a directory and its contents, you can use the rmdir function:

```
$directoryPath = 'path/to/delete';
rmdir($directoryPath);
```

Always be cautious when using rmdir, as it will only delete empty directories. You might need to recursively delete files and subdirectories if needed.

5. **Changing File Permissions:**

To change file permissions, you can use the chmod function:

```
$filePath = 'path/to/file';
chmod($filePath, 0644);
//Example:Give read and write permissions to the owner
```

You should be careful with changing permissions and ensure that it follows security best practices.

6. **Changing Directory Permissions:**

To change directory permissions, you can use the chmod function as well:

```
$directoryPath = 'path/to/directory';
chmod($directoryPath, 0755);
// Example: Give read, write, and execute permissions
```

Again, be cautious when changing permissions on directories.

7. **Checking File Permissions:**

You can check the permissions of a file or directory using the fileperms function:

```
$filePath = 'path/to/file';
$permissions = fileperms($filePath);
echo 'Permissions: ' . decoct($permissions);
```

The decoct function is used to convert the permission mode to octal representation for readability.

Always remember that when working with file and directory operations in PHP, the web server user (often www-data or apache) needs appropriate permissions to perform these actions. Ensure that you handle exceptions and errors gracefully, especially when dealing with file system operations, to prevent unexpected issues. Additionally, always validate and sanitize user inputs to prevent security vulnerabilities like directory traversal attacks.
